Abstract
Carbonic anhydrase (CA) activity in wheat leaves changed upon leaf dehydration: it decreased at mild stress (relative water content, RWC, 81 %), but increased at severe water stress (RWC 74 %). Phosphoenolpyruvate carboxylase activity was not significantly affected by these stresses.

Additional key words: leaf dehydration; phosphoenolpyruvate carboxylase; Triticum aestivum.

Reduction of photosynthetic carbon assimilation under water deficit is attributed to both stomatal closure and altered biochemical/photochemical reactions (for reviews see Kaiser 1987, Chaves 1991). We have recently distinguished between relative stomatal and nonstomatal limitations of wheat photosynthesis upon PEG-mediated water stress (Kicheva et al. 1994). It has been suggested that besides stomatal limitation a decreased mesophyll conductance to CO₂ transfer (gₘ) may limit photosynthesis when mild leaf dehydration is manifested. Some other results (Renou et al. 1990, Caemmerer and Evans 1991) point to the decreased gₘ causing considerably lower chloroplast CO₂ concentration in comparison to the intercellular CO₂ concentration (Ci) in dehydrated wheat leaves.

Since the CO₂ transfer conductance depends on CA activity at first place (Makino et al. 1992) and this activity might become limiting to photosynthesis under water stress (CA activity is unusually low in wheat), we have determined soluble CA activity in dehydrated wheat leaves.

Experimenter were carried out on second fully expanded leaves of 21 d old wheat (Triticum aestivum L. cv. Trakia) plants grown on nutrient solution in a growth

chamber (irradiance 160 μmol m⁻² s⁻¹, photoperiod 12 h, temperature 25±2 °C, relative humidity 60±5 %) (Kicheva et al. 1994). Leaf dehydration was achieved after submerging plant roots into 15 % (w/v) polyethylene glycol (PEG 6000) solution. The 6 and 24 h treatments caused decline in leaf RWC of about 10 % (mild water stress) and 20 % (severe water stress), respectively. Soluble CA activity was determined in leaf extracts by measuring the pH decrease at 2 °C with a pH electrode as described by Popova et al. (1996). Enzyme activity was defined as 1 unit = 10(t₀-t)/t, in which t and t₀ represent the time at 2 °C for a pH decrease from 8.3 to 7.8, with and without the enzyme, respectively. Phosphoenolpyruvate carboxylase (PEPC) activity was determined radiometrically (Popova et al. 1988).

The CA activity declined in response to mild leaf dehydration (Table 1). If CA activity in wheat is not present in great excess over what is required to maximise photosynthesis, then the decreased CA activity of about 18 % might affect the CO₂ diffusion towards carboxylation sites in the chloroplast. Therefore the chloroplast CO₂ concentration in the ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBPCO) vicinity would be lowered. This suggestion is supported by the fact that both the net photosynthetic rate and CA activity are decreased while C₃ remains constant in mildly dehydrated wheat leaves (this study and Kicheva et al. 1994).

Under severe leaf dehydration the CA activity increased by 67 % (Table 1). We hypothesise that CA could be involved in an alternative process of CO₂ fixation driven by PEPC. The finding that RuBPCO carboxylation activity is considerably decreased (Kicheva et al. 1994) while PEPC activity is not altered (Table 1) in severely dehydrated wheat leaves supports this interpretation (cf. also Popova et al. 1996). There is a strong evidence that cytosolic CA isozymes exist in C₃ plants (Fett and Coleman 1993, Suhlemeyer et al. 1993). The function of these isozymes can hardly be seen as facilitating CO₂ diffusion to the chloroplast because of the short distance between cell wall and chloroplast envelope and low concentration of HCO₃⁻ species in the nearly neutral cytoplasm (Cowan 1986).

All these results make the role of CA in water-stressed leaves an intriguing problem for further investigation. We believe that some additional pathway for inorganic carbon utilisation in C₃ leaves is potentially useful for plant survival under severe leaf dehydration when CO₂ input through the stomata is limited. Studies on CA protein expression in water-stressed wheat plants are in progress.
